Do Kalshi prices match what happened?

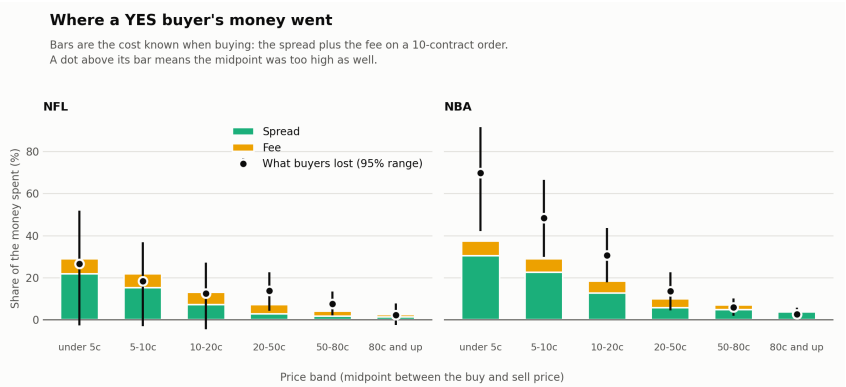

An actual-versus-expected study of 17,653 settled player-prop contracts from 88 NFL and NBA games, 5 October to 9 November 2026. Harrison Hong.

Bottom line. The data shows no measurable gap between Kalshi's prices and outcomes. Measured at the midpoint between the buy and sell price, contracts paid out within a few points of what the price implied, and what buyers lost was mostly the spread and the fee. With only 88 games, a gap of up to 4.5 points in a price band cannot be ruled out, so every result is reported with a range.

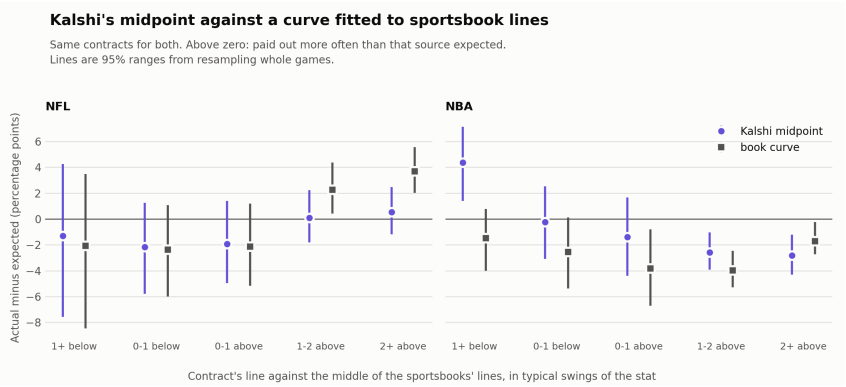

1. No measurable gap between prices and outcomes.
With both leagues together, contracts in every price band paid out within -2.0 to +0.9 points of the midpoint price, and no band's 95% range excludes zero. By league, the exception is NBA contracts under 5 cents: 1.7% paid out against 3.5% expected, on only 7 payouts. Longshot bands are thin: the under-5-cent band has 0.23 of full credibility, or 0.18 once contracts in the same game are allowed to move together. So this is not proof the prices were right: for contracts under 5 cents, priced at 3.6% on average, the true rate could be 2.1% to 4.3%.

2. What buyers lost was mostly the cost of trading.
Buying YES on every contract returned -9.9% (-14.2% to -5.9%). Of each dollar spent, 4.4% went to the spread, 3.0% to the fee on a 10-contract order, and 2.5% (-1.7% to +6.9%) to the midpoint being too high. The spread and fee, both known before buying, were 75% of the loss. Longshots cost the most: under 5 cents the spread alone took 24.4% and buyers returned -39.2%, against -2.5% at 80 cents and up. Dropping any one game leaves the overall return in the range -11.0% to -9.2%.

3. Kalshi matched a sportsbook-based curve, except on rare outcomes.
Overall accuracy was a tie: a Brier score of 0.1527 for Kalshi's midpoint and 0.1527 for a curve fitted to sportsbook lines (giving every contract the same chance scores 0.2251). On NFL lines far above the sportsbooks' middle, 5.2% paid out; Kalshi said 4.6% and the curve 1.5%. The curve is this study's own extrapolation, so this is a finding about the curve, not about sportsbooks.

Method. Prices were logged before each game by my own app from Kalshi's public API; results are Kalshi's settlements. The price bands and return formula were set at the start and not tuned to the results. Every 95% range comes from resampling whole games, because one player's contracts in a game win or lose together. The sportsbook curve was set from earlier seasons and not changed during the sample. **Limits.** Five weeks of one season; games I chose to scan; the YES side only; contracts settled part-way are left out. This is a study of prices, not betting advice. The analysis code is covered by tests.
